

Model structure conditions ecological inference in food web reconstruction

Tanya Strydom ¹; Baran Karapunar ²; Andrew P. Beckerman ¹; Alexander Dunhill ²

Abstract: Aim

Ecological networks are widely used to compare community structure, stability, and responses to disturbance across environmental gradients. However, many networks (particularly those assembled from incomplete interaction data) require model-based reconstruction. We test how alternative reconstruction frameworks condition ecological inference by quantifying their effects on network structure and disturbance dynamics.

Location

Cleveland Basin, United Kingdom.

Time period

Toarcian extinction event (Early Jurassic, late Pliensbachian–late Toarcian, ~183 Ma).

Major taxa studied

Marine animal communities.

Methods

We reconstructed four successive communities from an identical species pool using six contrasting food-web models spanning feasible (trait-based), realised (allometric and energetic), and structural (topological) network representations. For each community and model, 100 replicate networks were generated. We quantified macro-, meso-, and micro-scale network properties and assessed differences among models using multivariate analyses. Pairwise interaction turnover was measured using link-based beta diversity. We then simulated species loss under multiple disturbance scenarios, allowing cascading extinctions, and compared predicted community states using mean absolute differences and rank concordance metrics between models.

Results

Reconstruction framework strongly influenced inferred network topology (MANOVA, $p < 0.001$), generating distinct structural signatures independent of species composition. Models that were similar in global metrics often diverged in species-level interactions, with high -turnover among inferred link sets. During disturbance simulations, species-level vulnerability rankings were broadly consistent across models, but interaction-level outcomes and cascade dynamics varied substantially. Concordance in extinction-scenario rankings was scale dependent, with higher agreement at the species level than at the interaction level.

Main conclusions

Network reconstruction functions as a structural prior that conditions ecological inference. While some aggregate patterns are robust across modelling frameworks, detailed interaction-level dynamics are highly model contingent. Comparative network studies across spatial or environmental gradients should therefore align reconstruction framework with inferential goals and explicitly evaluate sensitivity to modelling assumptions.

¹ 1 Introduction

² Understanding how biodiversity is organised across space and time is a central goal of macroecology and
³ biogeography. While early efforts focused primarily on species richness and composition, there is growing
⁴ recognition that ecological communities are structured not only by which species occur, but by how they
⁵ interact (Thuiller et al., 2024). Interaction networks are increasingly treated as macroecological state variables
⁶ where they are used to compare community organisation across environmental gradients, to quantify -diversity
⁷ in interaction structure, to evaluate stability-complexity relationships, and to infer vulnerability under global
⁸ change (Carstensen et al., 2014; Gravel et al., 2019; Poisot et al., 2015; Trøjelsgaard & Olesen, 2016; Tylianakis
⁹ & Morris, 2017).

¹⁰ As a result, ecological networks now play a central role in comparative analyses spanning latitudinal gradients,
¹¹ disturbance regimes, and deep-time environmental transitions (Dunhill et al., 2024; Hao et al., 2025; Michalska-
¹² Smith & Allesina, 2019; Poisot & Gravel, 2014; Roopnarine, 2006). Implicit in this expansion is the critical
¹³ assumption that network properties estimated across systems are structurally comparable, and that differences
¹⁴ among them reflect ecological signal rather than methodological artefact (Fründ et al., 2016; Jordano, 2016).

¹⁵ Yet most ecological networks are not fully observed as interaction data are incomplete and sampling is
¹⁶ uneven across historical and biogeographic contexts, across both contemporary and deep-time (Catchen et
¹⁷ al., 2023; Poisot et al., 2021; Sandra et al., 2025). Interactions must often be inferred indirectly from traits,
¹⁸ phylogeny, body size, co-occurrence, or theoretical constraints (Morales-Castilla et al., 2015; Strydom et
¹⁹ al., 2021). Network construction therefore constitutes a model-based inference step rather than a purely
²⁰ descriptive exercise. Different reconstruction frameworks encode distinct ecological assumptions about how
²¹ interactions arise - whether as biologically feasible combinations of traits, energetically optimised realised diets,
²² or topological structures constrained by macroecological regularities. These assumptions act as structural
²³ priors over network architecture (Gauzens et al., 2025; Guimarães, 2020; Petchey et al., 2011; Strydom et
²⁴ al., 2026). If alternative reconstruction models systematically generate different trophic configurations, then
²⁵ comparative analyses risk conflating ecological differences among communities with artefacts introduced by
²⁶ modelling choice. The reliability of macroecological inference therefore depends not only on ecological data,
²⁷ but on the structural assumptions embedded in network reconstruction.

²⁸ Despite rapid methodological development in interaction inference, few studies have directly evaluated how
²⁹ alternative reconstruction frameworks condition macroecological conclusions when applied to the same species
³⁰ pool. This gap is particularly consequential for comparative research, where network metrics are routinely
³¹ interpreted as indicators of environmental filtering, disturbance intensity, evolutionary history, or community

32 stability (Allesina & Tang, 2012; Delmas et al., 2018; Poisot et al., 2015). If reconstruction models encode
33 distinct structural priors over interaction topology, then differences among communities may reflect modelling
34 assumptions rather than ecological processes. We therefore test whether macroecological inference derived from
35 ecological networks is robust to variation in reconstruction framework, asking which aspects of network-based
36 inference are stable across plausible representations of interaction structure and which are intrinsically model
37 dependent.

38 Deep-time ecosystems provide an especially stringent test of this issue because interactions are not observed
39 directly and must be reconstructed explicitly (Dunhill et al., 2024; Dunne et al., 2008; Dunne et al., 2014;
40 Roopnarine, 2006), rendering modelling assumptions transparent. Against this stringency, here we re-evaluate
41 inferences made by Dunhill et al. (2024) on community structure and extinction dynamics during the early
42 Toarcian extinction event (~183 Ma), a volcanic-driven hyperthermal and marine crisis in the Early Jurassic
43 (Kemp et al., 2024). Crucially, this re-evaluation allows us to test a pivotal but often overlooked possibility -
44 that the ecological narratives regarding community stability or collapse might be as much a product of the
45 specific reconstruction method chosen as they are of the fossil data itself. By applying alternative models,
46 we can determine if Dunhill et al. (2024) conclusions remain robust or if a different choice of reconstruction
47 method would have led to fundamentally different inferences about extinction dynamics. Using four successive
48 communities drawn from an identical taxon pool, we reconstruct ecological networks under six contrasting
49 model classes spanning feasible, realised, and structural representations. For each reconstruction framework,
50 we quantify emergent topology across scales, measure interaction turnover, and simulate disturbance-driven
51 collapse. By holding species composition constant while varying the food web model used, this design isolates
52 the influence of model constrained structure on inferred food web organisation and extinction dynamics,
53 allowing us to distinguish ecological signals that are robust from those that are reconstruction contingent.

54 2 Methods

55 2.1 Study system and fossil data

56 We used fossil occurrence data from the Cleveland Basin spanning the upper Pliensbachian to the upper
57 Toarcian. This interval encompasses a major volcanic-driven hyperthermal and marine extinction event. To
58 capture network dynamics across this transition, we defined four successive paleo-communities: Pre-extinction
59 (Pliensbachian), Post-extinction (Lower Toarcian), Early recovery, and Late recovery (Middle/Upper Toarcian).
60 Each taxon was characterized using their size and Bambach's ecospace framework (Bambach et al., 2007),
61 coding for tiering, motility, and feeding mode as per Dunhill et al. (2024). Each assemblage was treated

as a community of potentially interacting taxa. The dataset includes 57 taxa across diverse groups (*e.g.*, cephalopods, bivalves, and gastropods). By restricting our analysis to a single basin with consistent lithofacies, we controlled for biogeographic noise, ensuring that structural shifts across the four time-bins reflect localised ecological responses to environmental stress rather than sampling or facies bias.

2.2 Network reconstruction approaches

2.2.1 Conceptual classification of network types

Most paleo-specific research (*e.g.*, Fricke et al. (2022); Roopnarine (2006); Shaw et al. (2024)) currently uses models from within the feasibility space. That is, the model reconstructions identify and encode the entire feasible diet of a species to build the network. These methods, however, represent only a subset of the broader spectrum of network construction approaches. Here, we present a suite of methods (Table 1) that enable the construction of a wider range of ecological networks and the exploration of a broader set of ecological questions, provided that their underlying assumptions are compatible with the constraints of fossil data. The methods include a) structural models that create species agnostic networks that are structurally ‘correct’ by assigning links between nodes based on assumptions of link distributions; and b) realised models that create networks where links between species are constrained based on some form of ‘species choice’ *e.g.*, maximising energy gain.

Table 1: Six different models that can be used to construct food webs for both this specific community but are also broadly suited to paleo network prediction. These models span all facets of the network representation space (feasibility, realised, and structural network) and are suitable for an array of different paleo communities as the data requirements fall within the limitations set by the fossil record.

Model	Assumptions	Data needs	Limitation	Network type	Key reference	Usage examples
Random	Links assigned randomly	Species richness, number of links	Parameter assumptions, species agnostic	Structural	Erdős & Rényi (1959)	Null-model comparisons; testing whether observed network structure (connectance, motifs) deviates from random expectations
Niche	Species ordered along a ‘niche axis’; interactions interval-constrained	Species richness, connectance	Parameter assumptions, species agnostic	Structural	Williams & Martinez (2008)	Evaluating trophic hierarchy and motif structure; baseline structural predictions
Allometric diet breadth model (ADBM)	Energy-maximizing predator diets	Body mass, abundance/dance/biomass	Assumes optimal foraging; does not account for forbidden links	Realised	Petchey et al. (2008)	Predicting realized predator diets; exploring secondary extinctions

Model	Assumptions	Data needs	Limitation	Network type	Key reference	Usage examples
Allometric trophic network (ATN)	Links constrained by body-size ratios and functional response	Body mass, number of basal species	Assumes only mechanico/energetic constraints	Realised	Brose et al. (2006); Gauzens et al. (2023)	Simulating species loss; evaluating network collapse dynamics
Paleo food web inference model (PFIM)	Interactions inferred using trait-based mechanistic rules	Feeding traits	Assumes feeding mechanisms; trait resolution required	Feasibility	Shaw et al. (2024)	Mapping feasible trophic interactions; assessing secondary extinctions
Body-size ratio model	Probabilistic assignment of links based on predator-prey size ratios	Body mass	Does not account for forbidden links	Realised	Rohr et al. (2010)	Estimating likely interactions; simulating cascading effects.

78 The three body mass-based models (ADBM, ATN, Body-size ratio) differ primarily in their underlying
 79 ecological assumptions. Although all three models use body mass to infer food web structure, they differ in
 80 their ecological assumptions. The ADBM is based on energy maximization under optimal foraging theory,
 81 the ATN constrains interactions via mechanically optimal consumer-resource size ratios, and the Body-size
 82 ratio model defines links probabilistically within a fixed allometric niche. Together, these approaches span
 83 bioenergetic, mechanical, and statistical interpretations of size-structured interactions.

84 **2.2.2 Network generation and replication**

85 We evaluated six models spanning this space Table 1: random and niche models (structural networks);
86 allometric diet breadth (ADBM), allometric trophic network (ATN), and Body-size ratio models (realised
87 networks); and a paleo food web inference model (PFIM; feasibility network). Expanded descriptions of
88 model assumptions, parameterisation, and link-generation rules are provided in Supplementary Material
89 S1. For each community, 100 networks were generated per model per successive community ($n = 2400$) to
90 capture stochastic variation in link assignment. Where models required species body mass or trait values,
91 these were sampled within biologically reasonable ranges to preserve relative differences among species. We
92 adopted uniform sampling by default, as alternative distributions (lognormal, truncated lognormal) have
93 negligible impact on topology (Supplementary Material S2; Figure S1). Structural models were parameterized
94 using connectance values drawn from an empirically realistic range (0.07 – 0.34), with species richness held
95 constant. Identical parameter draws were applied across comparable models within each replicate to ensure
96 comparability. For the Body-size ratio model, we followed the approach of Yeakel et al. (2014) and excluded
97 latent trait terms as opposed fitting the full model, which introduces additional inference and assumptions.

98 **2.3 Network metrics and structural analyses**

99 We quantified network structure using a suite of macro-, meso-, and micro-scale metrics Table 2, capturing
100 global properties, motif structure, and species-level variability. Differences among reconstruction approaches
101 were assessed using a multivariate analysis of variance (MANOVA), with model identity as a fixed factor
102 and the full set of network metrics as response variables. Pairwise interaction turnover was quantified using
103 link-based -diversity following the framework of Poisot et al. (2012). For each pair of reconstructed networks,
104 we represented trophic interactions as binary adjacency matrices and calculated their dissimilarity. Specifically
105 we looked at interaction rewiring among shared species (β_{OS}), which allows separation of differences arising
106 from altered interaction identities among species common to both networks. All calculations were performed
107 for all model combinations within the same community (time bin).

Table 2: Network properties used for analysis.

Metric	Definition	Scale	Reference
Connectance	L/S^2 , where S is the number of species and L the number of links	Macro	

Metric	Definition	Scale	Reference
Max trophic level	Prey-weighted trophic level averaged across taxa	Macro	Williams & Martinez (2004)
S1	Number of linear chains, normalised	Meso	Milo et al. (2002); Stouffer et al. (2007)
S2	Number of omnivory motifs, normalised	Meso	Milo et al. (2002); Stouffer et al. (2007)
S4	Number of apparent competition motifs, normalised	Meso	Milo et al. (2002); Stouffer et al. (2007)
S5	Number of direct competition motifs, normalised	Meso	Milo et al. (2002); Stouffer et al. (2007)
Generality	Normalized standard deviation of generality of a species, standardised by L/S	Micro	Williams & Martinez (2000)
Vulnerability	Normalized standard deviation of vulnerability of a species, standardised by L/S	Micro	Williams & Martinez (2000)

108 2.4 Extinction simulations and model evaluation

109 Following Dunhill et al. (2024), we simulated species loss from Pre-extinction networks under trait-based,
 110 network-position-based, and random removal scenarios. Species were deleted sequentially, with cascading
 111 secondary extinctions allowed to propagate. Simulated post-extinction states were compared to ‘observed’
 112 networks using mean absolute differences (MAD) of food-web metrics Table 2 and modified true skill statistics
 113 (TSS) calculated separately at the node level (species presence/absence) and link level (presence/absence of
 114 interactions between species pairs). Scenarios were ranked within each reconstruction framework based on
 115 MAD and TSS performance, and Kendall’s rank correlation coefficient () was used to quantify concordance
 116 in scenario ordering across models. Full methodological details are provided in the Supplementary Materials.

117 **2.5 Software and Reproducibility**

118 Ecological network reconstruction and extraction of structural metrics were conducted in Julia v1.11.4
119 (Bezanson et al., 2017). All statistical analyses, model fitting (MANOVA, PERMANOVA, GAMs), and figure
120 production were performed in R v4.5.2 (R Core Team, 2024). The empirical data, derived network datasets
121 and code implementing network reconstruction, extinction simulations, and all analytical workflows is archived
122 at [Zenodo DOI].

123 **3 Results**

124 Results show that reconstruction approaches that appear similar when evaluated using global network metrics
125 can yield fundamentally different ecological narratives when interrogated at the level of interactions and
126 extinction dynamics. Across six network reconstruction approaches, inferred food web structure, species
127 interactions, and extinction dynamics differed consistently. Multivariate analyses showed pronounced separation
128 among models in network metric space. Reconstruction approach explained most of the variance in structural
129 properties, leaving a distinct signature independent of community composition. Notably, agreement among
130 models depended on the scale at which the comparison was made- approaches that were statistically similar in
131 multivariate structural space (scale 1) often diverged in inferred interactions (scale 2) or extinction dynamics
132 (scale 3). This demonstrates that structural similarity does not guarantee concordance in species-level diets or
133 trophic roles.

134 Model choice substantially influenced inferred extinction dynamics. Temporal trajectories of network collapse,
135 interaction loss, and motif reorganization differed among approaches. Although species-level extinction
136 rankings were often broadly consistent, link-level outcomes and extinction inferences were highly sensitive
137 to reconstruction assumptions. Together, these results show that ecological inferences drawn from networks
138 depend critically on the reconstruction framework employed.

139 **3.1 Network structure differs among reconstruction approaches**

140 Across six reconstruction approaches, network structure (network properties listed in Table 2) differed
141 significantly (MANOVA, Pillai's trace = 3.84, approximate $F_{40,11955} = 987.35$, $p < 0.001$), indicating that
142 model choice systematically alters inferred food web topology. Canonical discriminant analysis identified two
143 dominant axes of variation, explaining 86% of between-model variance. LD1 correlated with vulnerability,
144 direct competition motifs, and connectance. LD2 correlated with maximum trophic level and apparent
145 competition motifs, reflecting vertical trophic structure (Figure 1; Table S1, Figure S1). All higher-order

¹⁴⁶ canonical variates each explained less than 9% of the remaining variance.

¹⁴⁷ [Figure 1 about here.]

¹⁴⁸ **3.1.1 Variance partitioning of network structure**

¹⁴⁹ Permutational multivariate analysis of variance revealed that reconstruction framework accounted for the
¹⁵⁰ majority of variation in multivariate network structure ($R^2 = 0.795$, $p < 0.001$), whereas temporal turnover
¹⁵¹ across extinction phases explained a comparatively small proportion of variance ($R^2 = 0.064$, $p < 0.001$).
¹⁵² The model \times time interaction contributed a further 7.1% of variance ($R^2 = 0.071$, $p < 0.001$), indicating
¹⁵³ limited but significant time-dependent divergence among reconstruction frameworks. Thus, differences among
¹⁵⁴ modelling approaches were more than an order of magnitude greater than structural differences associated
¹⁵⁵ with ecological turnover through the extinction sequence, even if the Toarcian dataset was characterized with
¹⁵⁶ a significant community turnover.

¹⁵⁷ To determine whether the dominance of the reconstruction framework reflected absolute mean shifts among
¹⁵⁸ time bins, we repeated the analysis after centring network metrics within each extinction phase. This procedure
¹⁵⁹ removes between-phase differences while retaining within-phase structural variation. Even after temporal
¹⁶⁰ bin-standardised centring, the reconstruction framework explained 84.8% of multivariate variance ($R^2 = 0.848$,
¹⁶¹ $p < 0.001$). These results demonstrate that the influence of model choice is not driven by temporal mean
¹⁶² differences, but reflects intrinsic divergence among reconstruction frameworks in how ecological interactions
¹⁶³ are organised.

¹⁶⁴ **3.1.2 Statistical Drivers of Network Variation**

¹⁶⁵ The structural organization of the reconstructed food webs was dictated by the choice of modeling framework,
¹⁶⁶ which exerted a significantly stronger influence on network topology than the ecological signal of species loss.
¹⁶⁷ A two-way factorial ANOVA across all eight network metrics confirmed that the reconstruction approach
¹⁶⁸ was the dominant driver of variance, with partial eta-squared values (η_p^2) consistently exceeding 0.82 and
¹⁶⁹ reaching 0.97 for meso-scale motifs (Figure 2; Table S3). While the extinction event (time bin) significantly
¹⁷⁰ altered network structure ($p < 0.001$), its relative importance remained secondary, typically explaining a
¹⁷¹ smaller fraction of the total topological variation. This is clear in Figure 2 where all metrics are within the
¹⁷² bottom-right (model-dominated) quadrant of this space, emphasising that framework assumptions outweigh
¹⁷³ the ecological signal of species loss. Furthermore, the high inter-model Coefficient of Variation (CV) observed
¹⁷⁴ for some metrics (Table S4, Figure S4) highlights a sensitivity. The properties that are influenced by time
¹⁷⁵ are also those upon which the models disagree most profoundly. Demonstrating that our understanding of

176 structural food web collapse in the fossil record is highly contingent on the chosen reconstruction framework,
177 particularly when examining complex trophic pathways beyond simple macro-scale properties like connectance.

178 [Figure 2 about here.]

179 **3.1.3 Inferred pairwise interactions vary widely among models**

180 Despite some models showing similar global metrics, specific pairwise interactions often differed. Pairwise
181 -turnover revealed that certain model pairs shared very few links Figure 3. Size-based models (ADBM,
182 ATN) were broadly similar due to shared sole reliance on body-size constraints, whereas the Body-size ratio
183 model exhibited consistently higher differences to other models. PFIM showed intermediate overlap with
184 theoretical models. These results demonstrate that agreement in global network structure does not guarantee
185 concordance in species-level interactions.

186 [Figure 3 about here.]

187 **3.2 Model choice influences inferred extinction dynamics**

188 To evaluate how model choice affects inferred extinction dynamics, we compared simulated post-extinction
189 networks to observed networks using mean absolute differences (MAD) for network-level metrics and true
190 skills statistics (TSS) for node- and link-level outcomes Figure 4. Across models, MAD-based rankings were
191 generally positively correlated (Kendall's $\tau = 0.13$ across structural metrics), indicating broad agreement on
192 the relative importance of extinction drivers despite substantial differences in reconstructed network structure.
193 However, agreement within the allometric models differed from patterns observed for reconstructed network
194 structure.

195 Node-level TSS rankings were similarly consistent across models ($\tau = 0.26\text{--}0.90$), reflecting broadly comparable
196 species removal sequences. In contrast, link-level outcomes were far more variable ($\tau = -0.48\text{--}0.29$), highlighting
197 that inferences about which interactions are lost, retained, or re-established during collapse and recovery are
198 highly model contingent. Together, these results suggest that while alternative models converge on similar
199 species-level extinction patterns, the inferred pathways of interaction loss and cascading dynamics depend
200 strongly on both reconstruction approaches.

201 [Figure 4 about here.]

202 **4 Discussion**

203 **4.1 Network reconstruction is not neutral: structural priors shape ecological
204 theory**

205 Food web ecology has long treated network reconstruction as a technical step preceding ecological analysis.
206 Once a network is assembled (whether from observation, inference, or simulation) its properties are typically
207 analysed as reflections of underlying ecological organisation. Implicit in this workflow is a powerful assumption
208 - that reconstructed networks provide structurally comparable representations of ecological communities, such
209 that differences in connectance, trophic structure, motif composition, or robustness primarily reflect biological
210 variation.

211 This assumption is particularly critical to evaluate within the context of deep-time paleoecological data. Because
212 interactions in fossil ecosystems are never observed directly, they must explicitly be reconstructed through some
213 form of reconstruction approach. This necessity renders the underlying assumptions transparent but also makes
214 the resulting ecological narratives highly susceptible to the constraints inherent in the chosen reconstruction
215 framework. In these settings the risk is not just incomplete data, but the potential for methodological artefacts
216 to be misinterpreted as genuine macroevolutionary or paleoecological signals. Consequently, deep-time studies
217 offer a unique and stringent testing ground for determining whether community-level responses (such as
218 stability or collapse during mass extinctions) are robust features of the ecosystem or merely byproducts of
219 how we choose to construct the links between species.

220 Our results challenge this assumption and reveal strong sensitivity of inference about secondary extinction
221 dynamics in paleo-foodwebs. Across an identical species pool, reconstruction frameworks explained the majority
222 of variance among reconstructed network topologies, generating distinct structural signatures independent of
223 community composition. Demonstrating that the divergence among reconstruction approaches reflects intrinsic
224 differences in how models organise interactions, not temporal shifts in network structure. The dominance
225 of these structural signatures is systemic. Reconstruction frameworks occupy distinct and non-overlapping
226 regions of multivariate space Figure 1, with the model identity explaining nearly all of the observed variance.
227 Even when focusing on individual metrics, it is the choice of reconstruction approach that drives the observed
228 differences through the extinction interval Figure 2. This suggests that in paleo-food webs, the structure of
229 the network is pre-defined by the chosen reconstruction approach, leaving the extinction process to merely
230 reorganize the remaining links within a strictly pre-constrained architectural space. Network structure is
231 therefore not solely a property of ecological communities; it is jointly determined by ecological data, modelling
232 assumptions, and level of organisation (Gauzens et al., 2025; Guimarães, 2020; Pichler & Hartig, 2023;

²³³ Strydom et al., 2021; Strydom et al., 2026).

²³⁴ Reconstruction framework explained the majority of variance in inferred food web topology, far outweighing
²³⁵ the influence of temporal turnover across extinction phases. These patterns demonstrate that the divergence
²³⁶ among reconstruction approaches reflects intrinsic differences in how models organise interactions, not temporal
²³⁷ shifts in network structure. In other words, different reconstruction approaches impose distinct structural
²³⁸ priors on inference of ecological organisation. These priors are not subtle - they propagate into emergent
²³⁹ topology, species roles, and dynamical predictions. Network structure is therefore not solely a property
²⁴⁰ of ecological communities; it is jointly determined by ecological data, modelling assumptions, and level of
²⁴¹ organisation (Gauzens et al., 2025; Guimarães, 2020; Pichler & Hartig, 2023; Strydom et al., 2021; Strydom
²⁴² et al., 2026).

²⁴³ This has direct implications for the interpretation of comparative network studies. Feasible, realised, and
²⁴⁴ structural models encode different assumptions about constraint, optimisation, and topology, with these
²⁴⁵ assumptions propagating into emergent metrics and dynamical predictions (Allesina & Tang, 2012; Dunne et
²⁴⁶ al., 2002; Michalska-Smith & Allesina, 2019; Poisot & Gravel, 2014; Solé & Montoya, 2001). When networks
²⁴⁷ reconstructed under different model classes are compared across spatial gradients, disturbance regimes, or
²⁴⁸ evolutionary transitions, part of the observed variation may derive from reconstruction choice rather than
²⁴⁹ ecological process. Without explicit standardisation or sensitivity analysis, methodological heterogeneity can
²⁵⁰ be mistaken for biological signal. Food web ecology has devoted substantial effort to understanding how
²⁵¹ topology shapes dynamics; comparatively less attention has been paid to how reconstruction method shapes
²⁵² topology. Our findings indicate that these two questions cannot be separated.

²⁵³ 4.2 Scale-dependent robustness in network-based inference

²⁵⁴ Importantly, reconstruction sensitivity was not uniform across network scales (macro-, meso-, micro- level
²⁵⁵ properties). Species-level extinction rankings were broadly consistent among model classes, whereas interaction-
²⁵⁶ level outcomes and cascade trajectories were highly contingent on reconstruction approach. The predominance
²⁵⁷ of reconstruction framework over temporal turnover (~80% vs. 6% variance explained) illustrates why coarse-
²⁵⁸ grained patterns like species-level extinction rankings are more robust. Model-imposed structure dominates
²⁵⁹ the overall topology, leaving interaction dynamics highly contingent on framework choice. This asymmetry
²⁶⁰ reveals a context-dependent pattern of robustness. Coarse-grained macroecological patterns (such as the
²⁶¹ vulnerability of a community to collapse) can emerge from multiple plausible interaction architectures. By
²⁶² contrast, fine-grained inferences about which links are lost, retained, or reorganised depend strongly on how
²⁶³ interactions are inferred.

264 This distinction challenges a central ambition of food web ecology: the use of detailed interaction structure to
265 diagnose mechanisms of stability and collapse. Our findings suggest that while coarse-grained patterns might
266 be shared across methods, fine-grained mechanistic narratives (such as the specific pathways of interaction
267 loss) are much more precarious. This implies that had Dunhill et al. (2024) selected a different reconstruction
268 method, the resulting inferences regarding the drivers of extinctions could have pointed to entirely different
269 ecological mechanisms. If interaction-level cascade pathways vary substantially across equally plausible
270 reconstructions, then mechanistic narratives derived from a single inferred topology may overstate their
271 precision (Allesina & Tang, 2012; Curtsdotter et al., 2011; Dunne et al., 2002). The apparent determinism
272 of extinction cascades may therefore partly reflect reconstruction-imposed structure rather than ecological
273 inevitability.

274 For macroecology, this metric dependence clarifies where network-based inference is accurate. Aggregate
275 properties may be comparatively robust to reconstruction assumptions, whereas conclusions about interaction
276 turnover, motif reorganisation, or fine-scale trophic dynamics are intrinsically uncertain. Recognising this
277 asymmetry is essential if network analyses are to inform comparative synthesis across space and time.

278 Taken together, these results underscore that network reconstruction is not a neutral preprocessing step but
279 an additional part of the hypothesis-generating process in which each model encodes a distinct set of ecological
280 assumptions. The inferred topology and dynamics of a food web therefore reflect not only ecological data, but
281 the theoretical assumptions embedded in the reconstruction framework. Disagreement among models does
282 not imply that any single approach is ‘wrong’, but rather that different models capture different facets of
283 ecological reality (Petchey et al., 2011; Stouffer, 2019). Disagreement among models does not imply that any
284 single approach is ‘incorrect’. Rather, different models capture different facets of ecological constraint—trait
285 compatibility, energetic optimisation, or topological regularity. The critical point is that these facets are not
286 interchangeable.

287 This perspective reframes reconstruction choice as part of hypothesis specification. Researchers must align
288 reconstruction approaches with the ecological signals of interest (whether potential interactions, realised
289 diets, or macro-scale structural properties) rather than treating model selection as a technical convenience.
290 Viewed through the lens of accuracy and precision, our results indicate that some network-based inferences
291 are relatively robust across reconstruction approaches, whereas others remain intrinsically uncertain. High-
292 level extinction rankings were broadly convergent, suggesting relative accuracy at coarse resolution, but
293 interaction-level details and temporal cascade dynamics diverged substantially, indicating limited precision
294 in reconstructing the fine structure of collapse. Recognising and explicitly accounting for this distinction
295 is essential if food web ecology is to move beyond descriptive reconstruction toward rigorous comparative

296 inference.

297 4.3 Implications for comparative biogeography and global change research

298 Network approaches are increasingly applied to examine how ecological organisation varies across latitudinal
299 gradients, environmental filters, disturbance regimes, and climate-driven transitions (Gilman et al., 2010;
300 Tylianakis et al., 2008). In global change ecology, networks are used to project vulnerability under warming,
301 quantify rewiring of interactions, and assess stability under species loss (*e.g.*, Hao et al., 2025; Marjakangas et
302 al., 2025). These studies frequently interpret variation in connectance, trophic height, interaction -diversity,
303 or robustness as indicators of ecological differentiation among regions or time intervals (*e.g.*, Pellissier et al.,
304 2018; Trøjelsgaard & Olesen, 2016). Our results show that such differences can systematically alter inferred
305 topology and disturbance dynamics even when species composition is held constant. This suggests that
306 apparent differences in network structure across spatial or climate gradients may reflect variation in structural
307 priors as much as ecological process.

308 Deep-time paleo-food webs provide a complementary perspective because they capture ecosystem responses to
309 large-scale environmental perturbations and extinction events under past climate change (*e.g.*, Dunhill et al.
310 (2024); Smith et al. (2025)). Fossil networks therefore represent natural experiments for evaluating resilience,
311 trophic reorganisation, and recovery following extreme environmental change. Studies of fossil food webs have
312 demonstrated how network structure mediates extinction cascades and post-disturbance reassembly (Dunne
313 et al., 2008; Roopnarine, 2006), providing empirical constraints on long-term ecological stability.

314 However, our results emphasise that even in deep-time systems structural conclusions remain sensitive
315 to modelling assumptions. Treating reconstructed networks as ensembles rather than single deterministic
316 representations provides a more transparent framework for incorporating uncertainty into comparative
317 macroecology and for using paleo data to inform expectations about modern climate-driven reorganisation.

318 4.4 Toward a more explicit modelling paradigm in food web ecology

319 The broader implication is not that any single reconstruction framework is ‘correct’ or ‘incorrect’. Rather, each
320 model class represents a distinct hypothesis about how interactions are constrained—by trait compatibility,
321 energetic optimisation, or topological regularity (Petchey et al., 2011). Food web reconstruction is therefore
322 theory-laden. Making this explicit shifts reconstruction from a preparatory step to a central component of
323 ecological modelling.

324 A mature modelling paradigm in food web ecology would treat structural priors as testable assumptions,

325 incorporate probabilistic link inference where possible, and quantify the sensitivity of macroecological
326 conclusions to alternative representations of interaction structure. Such an approach aligns with recent
327 advances in probabilistic and ensemble network modelling and would strengthen the interpretability of
328 network-based inference under global change (Banville et al., 2025; Baskerville et al., 2011; Elmasri et al.,
329 2020; Perez-Lamarque et al., 2026; Poisot et al., 2016).

330 5 Conclusions

331 Ecological network reconstruction is not a neutral technical procedure but a theoretical act that shapes
332 ecological inference. By applying six contrasting reconstruction frameworks to an identical species pool, we
333 show that structural priors systematically influence inferred food-web topology, interaction identity, and
334 disturbance dynamics. Some coarse-grained patterns, such as relative species vulnerability, are comparatively
335 robust across representations. In contrast, fine-scale interaction structure and cascade pathways are highly
336 contingent on modelling assumptions. The reliability of network-based inference is therefore scale dependent.

337 These results challenge the implicit assumption that reconstructed networks are comparable across systems —
338 whether comparing modern communities across environmental gradients or fossil assemblages across extinction
339 intervals. When reconstruction frameworks differ, variation in connectance, trophic organisation, robustness,
340 or interaction turnover may reflect embedded modelling assumptions as much as ecological processes. Network
341 reconstruction should thus be treated as an explicit component of hypothesis specification in comparative
342 macroecology and biogeography.

343 No single model captures the full complexity of ecological organisation, but neither are alternative models
344 interchangeable. Aligning reconstruction framework with inferential goals, standardising approaches across
345 comparative studies, and incorporating ensemble or probabilistic representations will be essential for strength-
346 ening the interpretability of network analyses across spatial and temporal gradients, including efforts to
347 use deep-time systems to inform expectations under contemporary climate change. As ecological networks
348 increasingly inform global change research, recognising model reconstruction as fundamental determinants of
349 inference is critical for advancing food web ecology from descriptive reconstruction toward rigorous comparative
350 synthesis.

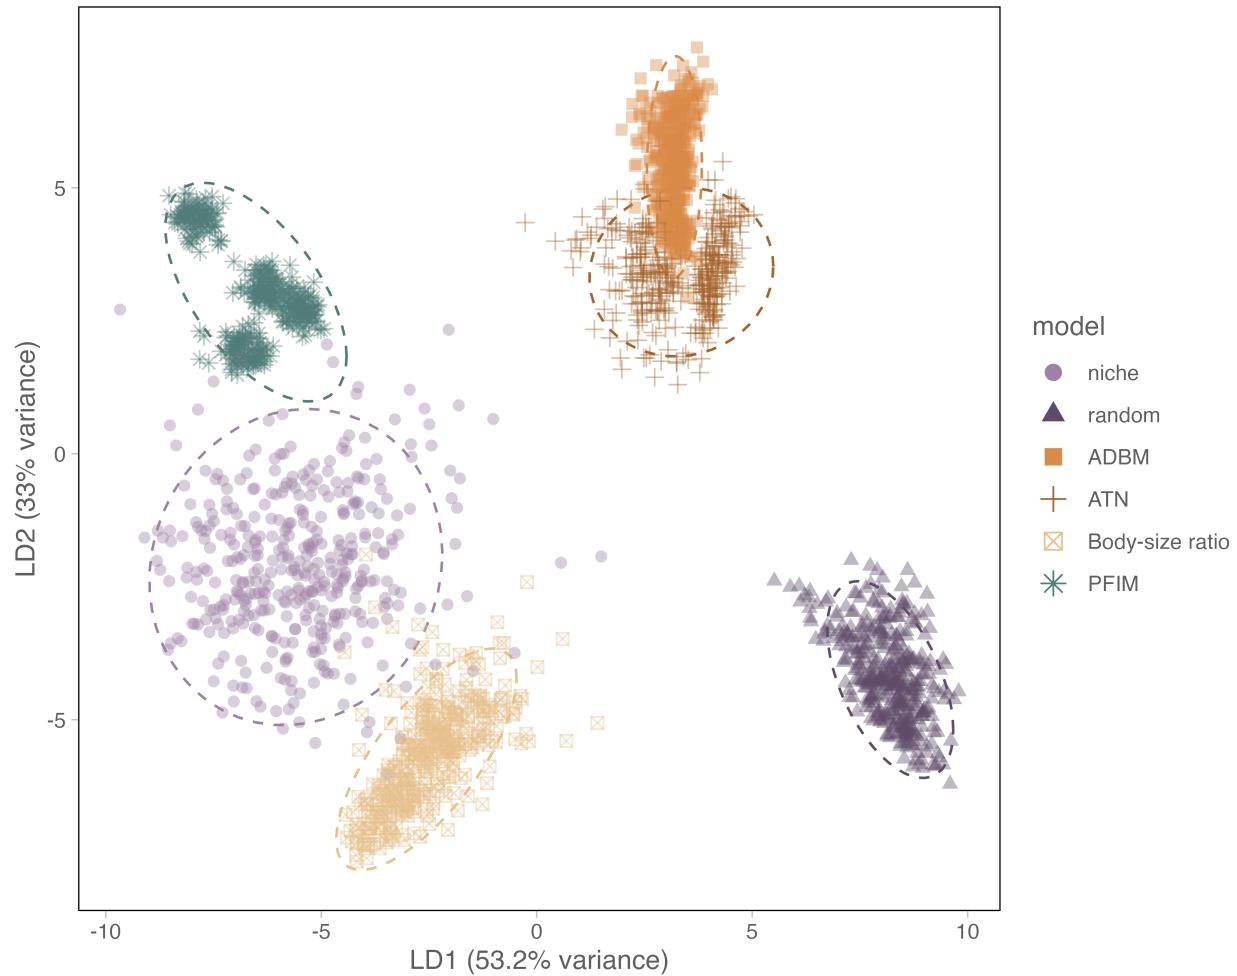

Figure 1: Linear discriminant analysis (LDA) of ecological network metrics for six model types. Each point represents a replicate, and ellipses indicate 95% confidence regions for each model. The second column represents the correlation of the various network metrics with the respective LDA axes.

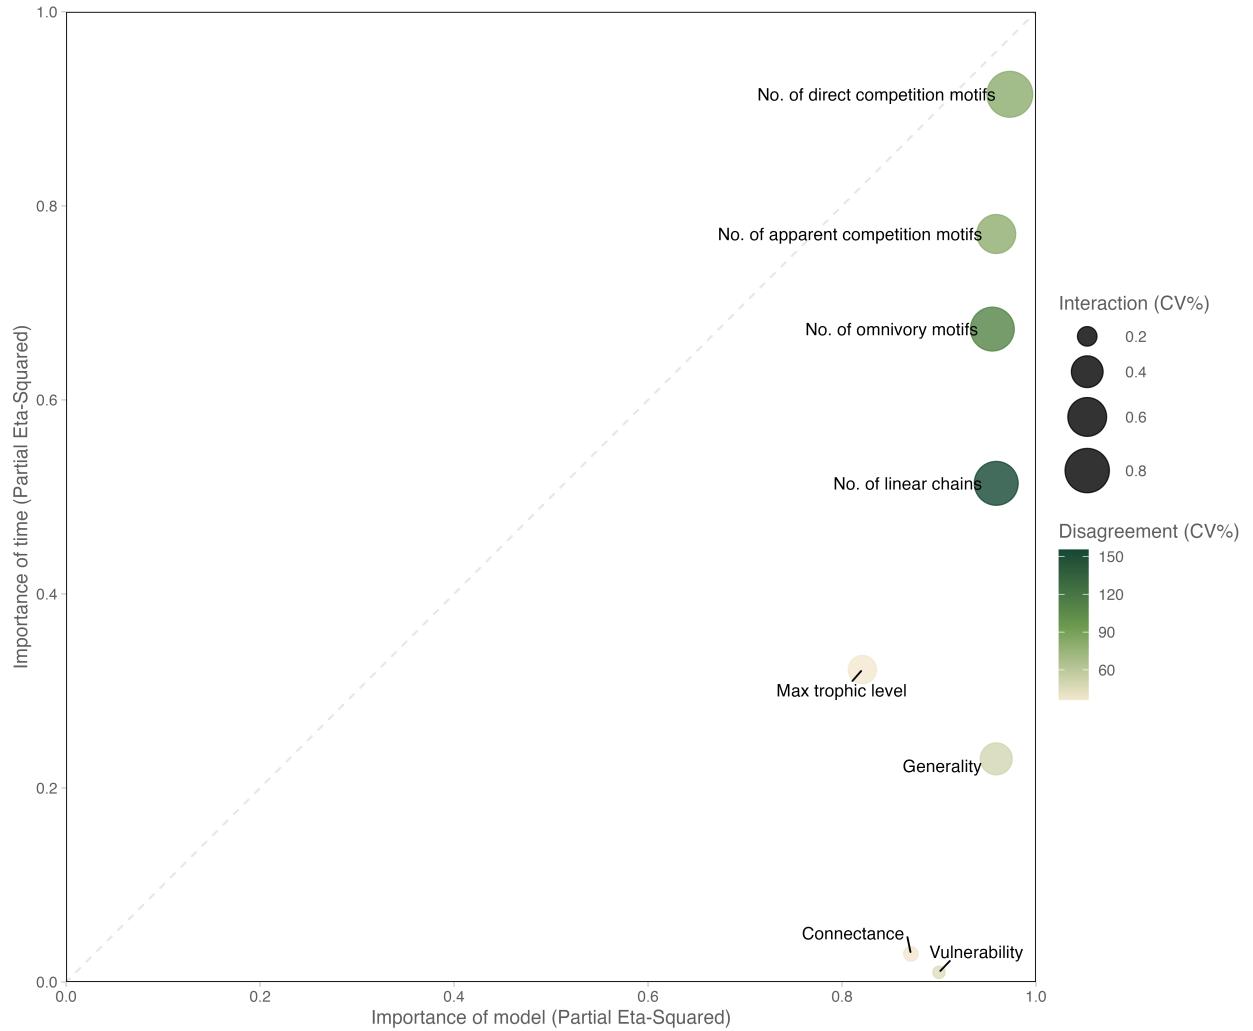

Figure 2: Scatter plot illustrating the influence of model (x-axis) and time (y-axis) across network metrics. The dashed 1:1 diagonal represents the parity of influence; metrics below this line are governed primarily by model choice and those above by time. Bubble size indicates the interaction between model and time while colour indicates inter-model disagreement (Mean CV%); greener bubbles signify metrics where models show the highest divergence in their structural predictions.

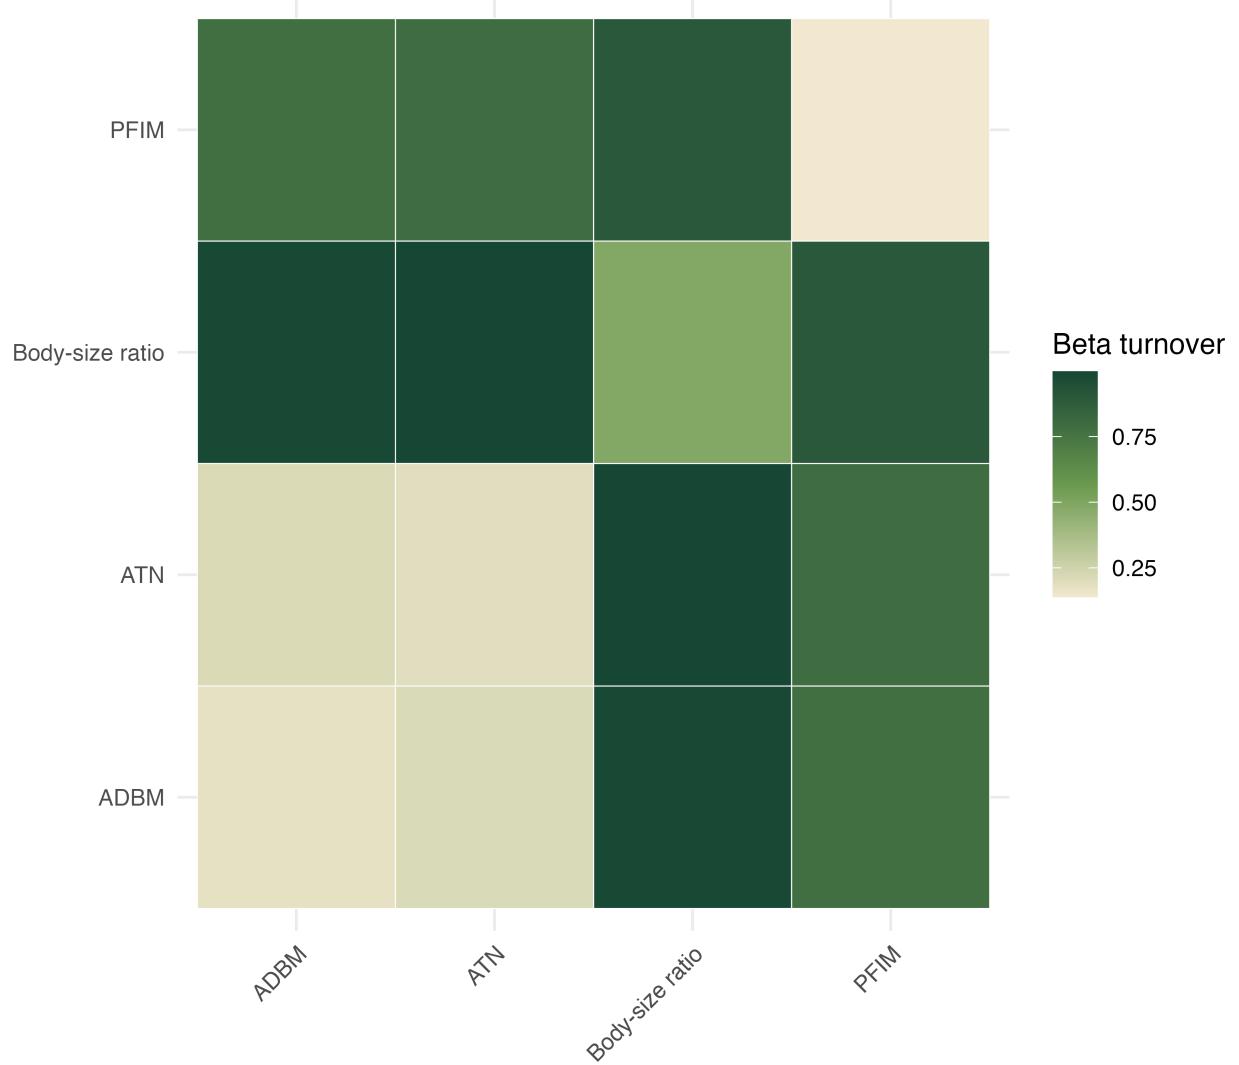

Figure 3: Pairwise β -turnover in species interactions among four ecological network models (ADBM, ATN, Body-size ratio, and PFIM). Each cell represents the mean turnover value between a pair of models, with darker colours indicating greater dissimilarity in inferred interactions. High turnover values indicate strong disagreement in pairwise interactions between models, whereas lower values indicate greater similarity.

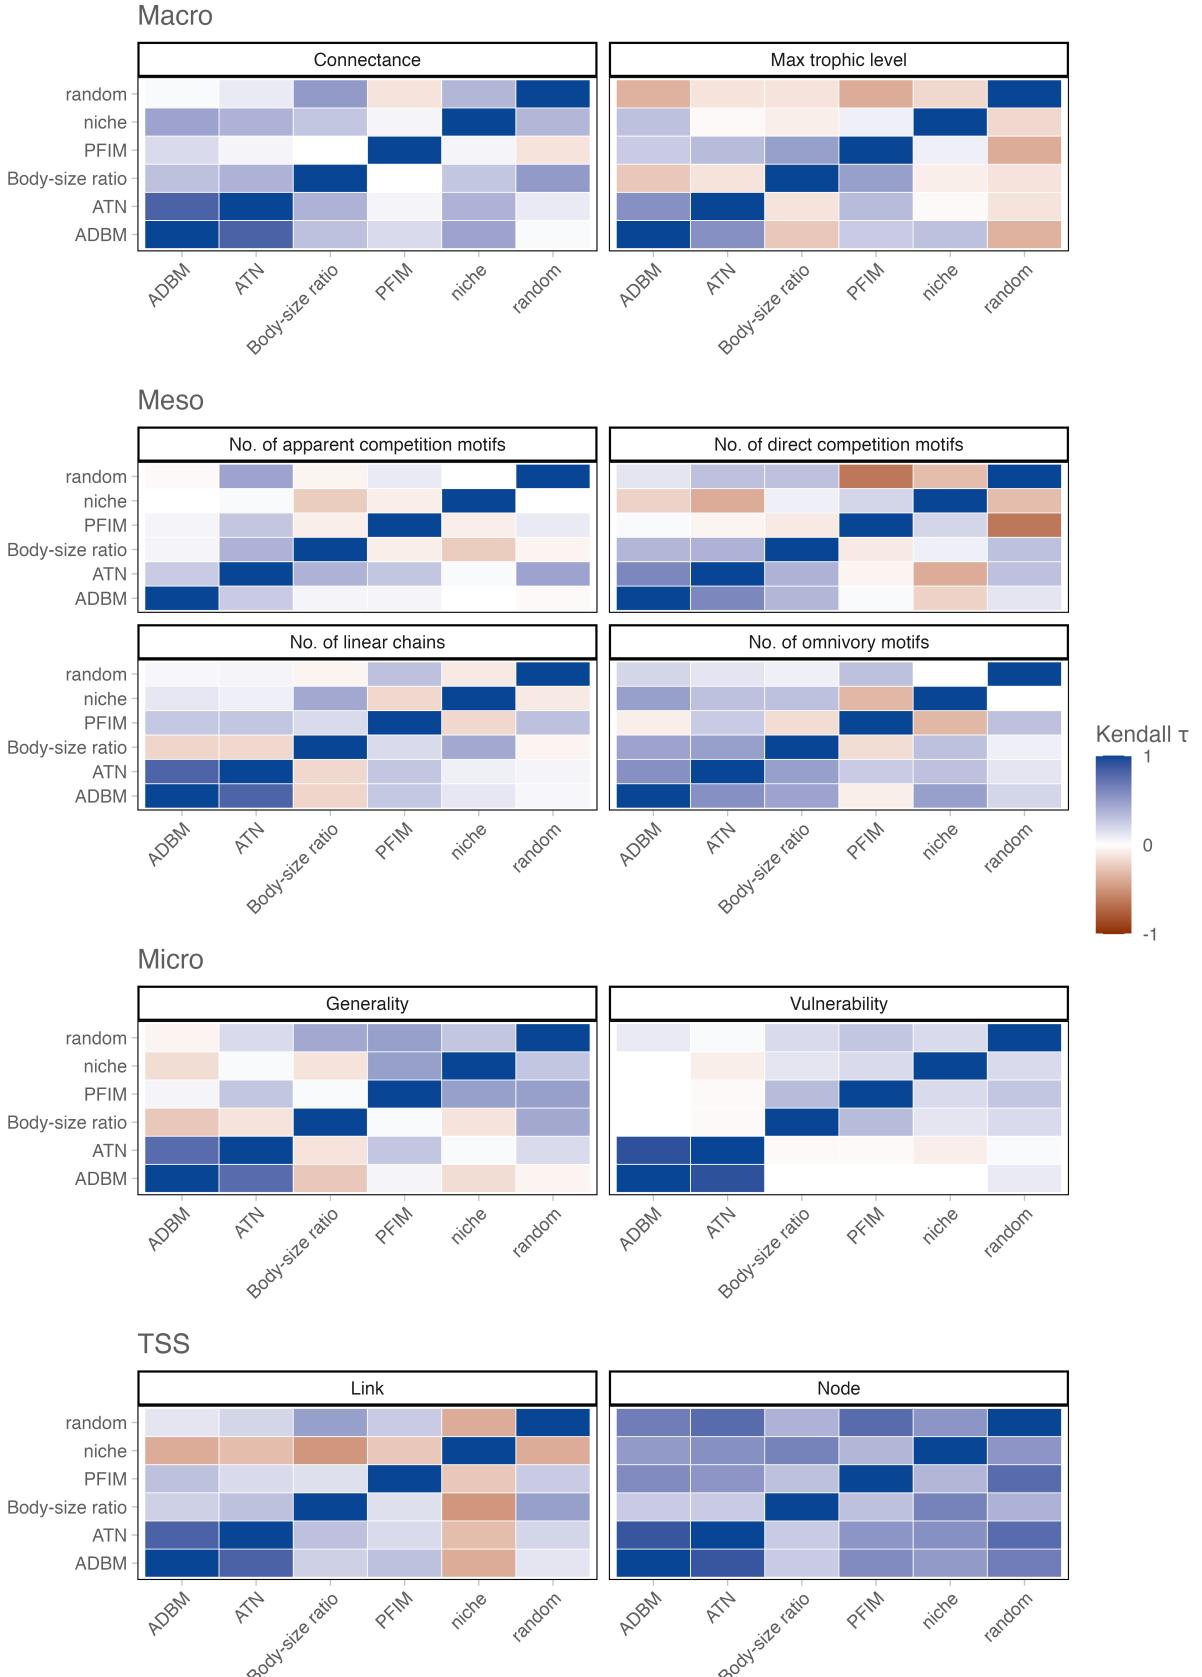

Figure 4: Heatmaps showing pairwise Kendall rank correlation coefficients (τ) between models for each network metric. Each panel corresponds to a different metric and displays the degree of agreement in extinction-scenario rankings across models based on mean absolute differences (MAD) between observed and predicted network values. Positive τ values (blue) indicate concordant rankings between models, whereas negative τ values (red) indicate opposing rankings. Warmer colours approaching zero represent little or no agreement.
